Exploration of power and treatment effect precision using an adjusted analysis for a randomised controlled trial (Bayesian & frequentist)

Eamonn O'Brien
01 August, 2016

1 Introduction

Many randomised controlled trials (RCTs) are analysed in a simple manner using only the randomised treatment as the independent variable. But when the response outcome is continuous, precision of the treatment effect estimate is improved when adjusting for baseline covariates in a randomised controlled trial. We do not expect covariates to be related to the treatment assignment because of randomisation, but they may be related to the outcome, they are therefore not considered to be confounding. However, differences between the outcome which can be attributed to differences in the covariates can be removed, this results in a more precise estimate of treatment effect. This should be considered more often as sample sizes can be reduced. This is not the case for logistic models (principle of the non collapsibility of the odds ratio).

Here, we perform an investigation of adjusted and unadjusted power in the setting of a RCT. We then choose a sample size and simulate a single RCT. The RCT is then analysed using a frequentist approach and a Bayesian approach.

2 Prepare for stochastic simulations

```
alpha <- 0.05
n.sims <- 200  # simulations
N <- seq(from=100, to=1000, by=50)  # trial sizes to explore
pow.adj1 <- pow.adj2 <- pow <- rep(NA, length(N)) # object to capture summary power estimates
bias <- array(NA, dim=c(length(N),6))  # object to capture summary coeff estimates</pre>
```

3 Function to investigate power for a RCT contingent on the analyses perfored (adjusted and unadjusted)

```
for (j in 1:length(N)){
   n <- N[j]

#objects to collect simulations for each sample size before summary stats are calculated
   significant.unadjusted <- significant.adj1 <- significant.adj2 <- rep(NA, n.sims)
   est <- array(NA, dim=c(n.sims,6))

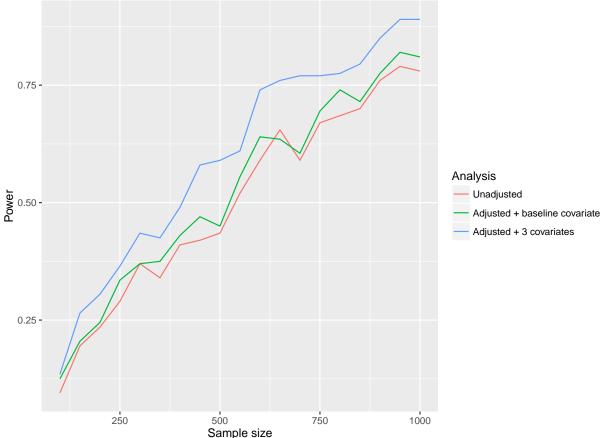

for (i in 1: n.sims){</pre>
```

```
# Hyp the effect of age on outcome, a unit change in outcome over the whole age range,
   # so ~0.02 effect on outcome for each increase in age of 1 year
   effect.of.age \leftarrow 1/(65-18)
   effect.of.sex <- 5
                                       # Hyp the effect of sex on outcome
   effect.of.treatment <- 1
                                     # Hyp the treatment effect on outcome
   # Hypothesize baseline version of response on outcome,
   # a unit increase results in 0.5 increase in outcome,
   # strong predictor so 5 over the baseline range
   effect.of.baseline <- 1/2
   intercept <- 100</pre>
   noise <- 5
                                       # random error
   #collect the true parmaeters to see how well we recover them
   covp <- c(intercept, effect.of.baseline, effect.of.sex,</pre>
             effect.of.age, effect.of.treatment, effect.of.treatment)
# covariate effects
baseline \leftarrow runif(n,100,110)
                                                  # baseline effect
treat \leftarrow 1*(runif(n)<0.5)
                                                  # randomised treatment effect
sex <- c(rep("F", n/2), rep("M", n/2))
                                                 # Generate sex covariate
age <- sample(x=18:65, size=n, replace=TRUE) # Generate age covariate
# create the outcome, with random error
Y <- effect.of.sex*(sex=="M") + effect.of.age*age + effect.of.baseline*baseline +

```

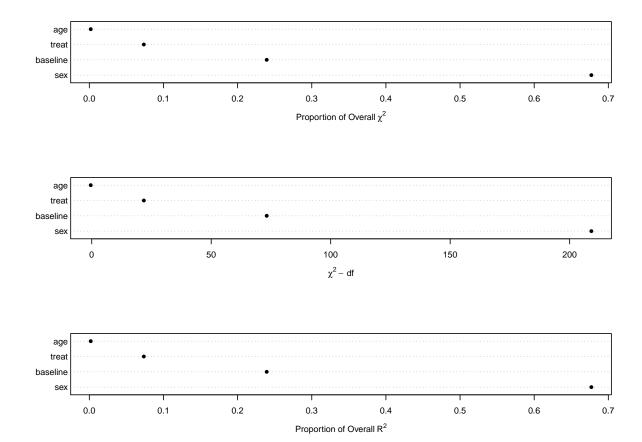

Figure 7: The default for plot(anova()) is to display the Wald Chi2 statistic minus its degrees of freedom for assessing the partial effect of each variable. Even though this is not scaled [0,1] it is probably the best method in general because it penalizes a variable requiring a large number of parameters to achieve the Chi2. If a predictor interacts with any other predictor(s), the Chi2 and partial R2 measures combine the appropriate interaction effects with main effects. For example if the model was $y \sim$ biomarker * treatment the statistic for treatment is the combined effects of treatment as a main effect plus the effect modification that treatment provides for the biomarker effect. This is an assessment of whether there is a difference between the treatment for any biomarker score.
